We show that a slowly decaying current pulse can lead to nearly deterministic precessional switching in the presence of noise. We consider a biaxial macrospin, with an easy axis in-plane and a hard axis out-of-plane, typical of thin film nanomagnets patterned into asymmetric shapes. Out-of-plane precessional magnetization orbits are excited with a current pulse with a component of spin polarization normal to the film plane. By numerically integrating the stochastic Landau-Lifshitz-Gilbert-Slonczewski equation we show that thermal noise leads to strong dephasing of the magnetization orbits. However, an adiabatically decreasing pulse amplitude overwhelmingly leads to magnetization reversal, with a final state dependent on the pulse polarity. We develop an analytic model to explain this phenomena and to determine the pulse decay time necessary for adiabatic magnetization relaxation and thus deterministic magnetization switching.

I. INTRODUCTION

The study of spin-current driven magnetic excitations has been a very active area of research over the past decade and has significant technological applications [1,2]. Specifically, the excitation of magnetization precession has led to current controlled oscillators that operate at GHz frequencies [3] and spin-current driven magnetization reversal has led to the development of nonvolatile magnetic memory devices [4]. Spin currents create spin-transfer torques (STT) that provide a means of exciting and driving nonlinear magnetization dynamics of nanometer scale magnets (or nanomagnets). The magnetization dynamics is also strongly affected by the presence of thermal noise which can alter the stability of magnetization states and the nature of the spin-transfer induced dynamics, including precessional magnetization orbits.

Typically the magnetization dynamics consist of a fast gyromagnetic precession, whose amplitude slowly changes over time due to spin torque and thermal effects. This separation of time scales can be used to study analytically the dynamical and thermal stability of nanomagnets subject to spin-polarized currents [5–7], and allows for a reduction in complexity of the stochastic Landau-Lifshitz-Gilbert-Slonczewski (sLLGS) equations to a simpler one-dimensional stochastic differential equation. In the absence of damping, spin torque, and thermal noise, the dynamics conserve the macrospin energy, but in their presence a macrospin’s dynamical evolution deviates from a constant energy trajectory.

Thus an analysis of the noise-induced dynamics obtained by averaging the magnetization equations over constant-energy orbits provides significant new insights. Some of the authors of this paper have done this for a biaxial nanomagnet with an easy axis in the film plane and a hard axis out of the plane, typical of thin film nanomagnets patterned into asymmetric shapes (e.g., an ellipse) [6,7]. Relevant dynamical scenarios have been shown to depend on the ratio between hard and easy axis anisotropies. The range of currents for which limit cycles exist was found, and the constant energy orbit averaging approach was used to study the magnetization dynamics of spin-torque oscillators, both in the presence of thermal noise and as a function of the spin-polarization angle in a biaxial macrospin model [6]. For this case analytical expressions were derived for currents that generate and sustain the out-of-plane precessional states. Furthermore, there is a critical angle of the spin polarization necessary for the occurrence of such states. We also predicted a hysteretic response to applied current [7], which was tested in experiments on orthogonal spin-transfer devices [8], where the predicted hysteretic transitions into an intermediate resistance state were observed [9].

Here we consider STT magnetization switching that occurs by out-of-plane precessional magnetization dynamics, as can occur in an orthogonal spin-transfer device. For this case it was widely thought that thermal and other noise sources would lead to dephasing of the precessional motion and thus an indeterminate magnetic state after the pulse ends. Here we demonstrate and explain a rather unexpected result that when the decay of a spin-current pulse is sufficiently slow the switching is very reliable even in the presence of noise, with the current pulse polarity determining the final magnetization state. After introducing our model for a biaxial nanomagnet and its dynamical modes we consider the effect of the pulse switching probability by numerically integrating the sLLGS equations and then describe our analytic model which explains the origin of the highly reliable switching.

The paper is structured as follows. In Sec. II we introduce the basic physics of the biaxial macrospin model, its energy landscape, as well as dynamical effects of spin-transfer torques and thermal noise. We discuss the energy of the magnetization orbits that separates in-plane and out-of-plane precessional states (the separatrix), summarizing the previously studied features of the model such as switching behavior, out-of-plane precessional steady states, and critical currents. We then present numerical simulations of current induced magnetization dynamics, demonstrating that a slowly
decaying current pulse can lead to reliable switching of the magnetization. Subsequently, we introduce a model that can qualitatively explain this phenomenon. In Sec. III we project the macrospin’s dynamical equation onto the separatrix and study these projected dynamics as a function of current intensity. In so doing we show how, for current intensities greater than a threshold, the dynamics orthogonal to the separatrix lead to a net drift of the magnetization towards one of the two in-plane basins depending on the current polarity. We call this effect “orthogonal drift biasing.” This biasing favors magnetization relaxation into a given in-plane basin as long as the currents driving it are above a threshold as it transits across the separatrix. In Sec. IV we employ the constant energy orbit averaging techniques to show that if pulse decay time scales are larger than those for magnetization relaxation onto a given steady-state orbit, we argue that this explains our numerical results on magnetization switching with exponentially decaying current pulses. Finally, in Sec. VI we show in numerical simulations that the switching behavior depends on the decay time of the pulse and not on the maximum current intensities.

II. MACROSPIN MODEL WITH SPIN-TRANSFER TORQUES

We study a macrospin with magnetization $\mathbf{M}$ of constant modulus ($M = |\mathbf{M}|$) with a biaxial magnetic anisotropy, with easy direction along the $\hat{x}$ axis and hard direction along $\hat{z}$. Its energy landscape depends on the projection of the magnetization onto these two axes [10]. We write the easy and hard axis anisotropy energies as $K_E = \mu_0 M_s H_K V/2$ and $K_H = \mu_0 M_s M_{\text{eff}} V/2$, where $H_K$ is the anisotropy field, $M_{\text{eff}}$ is the effective easy-plane anisotropy field, which is of order $M_s$ when this anisotropy has its origin only in the shape of the magnetic element [11], and $V$ is the volume of the magnetic element. In the absence of external magnetic fields and magnetic dipole fields arising from other magnetic layers, the energy can be written as

$$E(\mathbf{m}) = K_E[Dm_z^2 - m_x^2],$$

where $\mathbf{m} = \mathbf{M}/|\mathbf{M}|$ is the normalized magnetization vector and $D \equiv K_H/K_E = M_{\text{eff}}/H_K$ is a dimensionless ratio of the hard and easy axis anisotropies. $m_x$ and $m_z$ are the projections of the normalized magnetization vector on the x and z axis, i.e., $\mathbf{m} \cdot \hat{x}$ and $\mathbf{m} \cdot \hat{z}$, respectively. This energy has minima and thus stable magnetic configurations for $\mathbf{m}$ parallel and antiparallel to $\hat{x}$, with an energy barrier $U = K_E$ separating these states. The out-of-equilibrium dynamics are described by the sLLGS equation:

$$\dot{m}_x = A_I(\mathbf{m}) + B_{ik}(\mathbf{m}) \circ H_{h,k},$$

where the stochastic contribution $H_{h,k}$ is taken to have zero mean and delta-function correlation $(H_{h,i}(t)H_{h,k}(t')) = 2C_\delta \delta(t-t')$. The diffusion constant $\alpha = \alpha/[2(1+\alpha^2)]$, with $\alpha$ the Landau damping constant (typically $\ll 1$), $\xi \equiv U/k_B T$ the energy barrier height divided by the thermal energy, is chosen to satisfy the fluctuation-dissipation theorem, and multiplicative noise “$\circ H_{h,k}$” is interpreted in the Stratonovich sense [12]. The expressions for the drift vector $\mathbf{A(m)}$ and diffusion matrix $\mathbf{B(m)}$ terms read

$$A(\mathbf{m}) = \mathbf{m} \times \mathbf{h}_{\text{eff}} - \alpha \mathbf{m} \times (\mathbf{m} \times \mathbf{h}_{\text{eff}}) - \alpha l \mathbf{m} \times (\mathbf{m} \times \mathbf{n}_p) - \alpha^2 / m \times \mathbf{n}_p,$$

$$B_{ik}(\mathbf{m}) = -\epsilon_{ijk} m_j - \alpha (m_i m_k - \delta_{ik}),$$

where $\mathbf{h}_{\text{eff}} = -\frac{1}{\mu_0 M_s H_K} \nabla_m E(\mathbf{m})$ is the effective field rescaled by $H_K$, $\alpha$ is damping constant, and $\mathbf{n}_p$ is the axis along which the spin current is polarized. STT effects due to current density $J$ (in units of $A/m^2$) are written in terms of a rescaled dimensionless current $I = (h/2e)\eta J/(\mu_0 M_s H_K t)$, where $\eta$ is the thickness of the magnetic free layer and $\eta = (J_1 - J_2)/(J_1 + J_2)$ is the spin polarization. The effect of a STT depends on $\omega$, the angle between the spin-polarization axis $\mathbf{n}_p$ and the easy axis $\hat{x}$ [see Fig. 1(a)] [13]. The temporal derivatives appearing in (2) and throughout this paper are with respect to the natural time scale $\tau = \gamma \mu_0 H_K t/(1+\alpha^2)$, where $\gamma$ is the gyromagnetic ratio. The dynamics associated with Eq. (2) [14–16] leads to a Boltzmann equilibrium distribution of the magnetization at long times.

We note that in most experiment situations the spin-transfer torque associated with the current [the third term on the right-hand side of Eq. (3)] is small compared to the precessional torque [the first term on the right-hand side of Eq. (3)]. In this case the precessional time scale is much smaller than that of spin-transfer torque, damping, and thermal diffusion, allowing Eq. (2) to be effectively reduced to a 1D stochastic differential equation for the evolution of the macrospin’s instantaneous energy $E$ as a function of time $[5,17]$. The current range in which this is valid is discussed in [7] and the analysis conducted in this paper considers this small spin-transfer torque and thus current limit. This approach has proven to be useful because it allows the macrospin’s dynamics...
to be characterized analytically in many interesting physical situations, which we now summarize.

**Biaxial macrospin model**

In the absence of damping, spin torque, and thermal noise, the dynamics (2) preserve the macrospin’s energy, which, expressed in dimensionless form, reads

\[ \epsilon = \frac{E(m)}{U} = Dm_z^2 - m_x^2. \]

The conservative trajectories come in two different types. For \(-1 < \epsilon < 0\) the magnetization gyrates around the easy \(\hat{x}\) axis and is said to be precessing “in-plane” (IP). For \(0 < \epsilon < D\), the magnetization precesses about the hard \(\hat{z}\) axis and is said to be precessing “out-of-plane” (OOP). A sample of these trajectories for positive and negative energies is shown in Fig. 1(b).

Upon introducing the effects of damping, the dynamics will dissipate magnetic energy, thus mapping any initial state of the configuration sphere into a corresponding final state either aligned parallel (P) or antiparallel (AP) with the easy \(\hat{x}\) axis. Figure 2 shows a projectional map of the Bloch sphere color coded according to the state to which the magnetization relaxes; \(D = 10\) and \(\alpha = 0.04\) was chosen for the plot and white/black regions correspond to P/AP final states respectively. In Figs. 3(a) and 3(b) the Bloch sphere of an identical macrospin model relaxes in the presence of thermal noise with intensity \(\xi = 1200\) and \(\xi = 80\) (larger \(\xi\) corresponds to lower temperature). We omit the Molleweide axes labels in this and subsequent figures as they are identical to those used in Fig. 2. Thermal effects can be seen to modify the zero temperature relaxation shown in Fig. 2 by blurring the boundaries of the white and black regions; the relaxation process becomes stochastic.

The introduction of a driving current will strongly affect the magnetization dynamics due to the additional spin-transfer torque biasing either the P or AP basins. We note that this is generally a nonconservative torque and thus its effects cannot be described in terms of the gradient of an effective energy. This renders many techniques used to analyze the energetics involved in the macrospin’s evolution inapplicable. However, previous work has shown that whenever the time scales for thermal and spin-torque driven diffusion are much larger than the conservative precessional time scale, nonconservative
effects can be studied perturbatively [5,6,16]. Effectively, the macrospin precesses multiple times along nearly constant energy trajectories, only diffusing slowly in energy. This allows for an averaging of the LLGS dynamics (2) along constant energy trajectories [shown in Fig. 1(b)] to obtain a description of the macrospin’s dynamics solely in terms of diffusive behavior over its conservative energy landscape [6]. An analysis of the time evolution of the macrospin’s energy provides significant insights into magnetization dynamics in the presence of STT.

We summarize the main results of such an analysis, the details of which can be found in Refs. [6,7]. There are two fundamental features of a biaxial macrospin subject to a spin current. The first is that there are two critical currents ($I_c$ and $I_{OOP}$). For currents $I > I_c = (2/\pi)\sqrt{D(D + 1)}/\cos \omega$ the entire AP basin becomes unstable ($k > 0$ for all $\xi < 0$) and magnetic states within it will be driven into the OOP basin. This result is in remarkable contrast to what was seen [19]. Conversely, for supercritical tilts, the current can be increased such that $I > I_{OOP}$. If the current is increased sufficiently slowly (so that the constant energy orbit approach applies), magnetizations in the AP state will evolve toward the P basin or, if $I > I_{OOP}$, remain in the OOP basin. Those near the AP state did not have the pulse been left on for a longer time there would been fewer not-switched states in this zone. In the supercritical case the large tilt allows the current to excite all IP states into OOP orbits where thermal noise and dynamical decoherence shuffle the trajectories enough that, once relaxation takes place in the absence of a current, the final states appears random.

Having seen the characteristic switching dynamics in the presence of noise for sub- and supercritical tilts, we now investigate a case in which the driving current is switched off gradually as opposed to the stepwise fashion we have considered up to this point. We again consider a pulse that is turned on for a time $0.27\,\text{ns}$ and decays exponentially, $I(t) = I_0 \exp(-t/\tau_I)$. The pulse thus decays from a value $I_0 > I_c > I_{OOP}$ with a time constant $\tau_I$. We again sample the entire Bloch sphere and determine to what state the magnetization relaxed in the presence of noise.

Figure 4 shows the relaxation behavior for $D = 10$, $\alpha = 0.04$, $\omega = 2.5\omega_0$, at different temperatures ($\xi = 5714, 80$ corresponding to left/right column, respectively) and current decay time scales ($\tau_I = 0.01, 0.07, 0.15\,\text{ns}$ from top to bottom). As the decay rate is made progressively larger, the Bloch sphere is seen to overwhelmingly relax into the P basin. This result is in remarkable contrast to what was seen in Fig. 3(d). The current pulse is sufficient to excite OPP orbits yet if the pulse decay time is sufficiently slow the magnetization relaxes reliably into a state set by the current polarity (positive current in our model favors the P state). The effect is more pronounced at lower temperatures [compare Figs. 4(c) and 4(f)].

To further highlight the role of the pulse relaxation time and the temperature in this phenomena, we show the switching probability for three different temperatures ($\xi = 5714, 1200,$ and 80) as a function of the pulse relaxation time $\tau_I$ in Fig. 5. It is clear that the effect is robust as a function of temperature but the switching probability increases on reducing the temperature. We further find that the switching probability is nearly independent of the pulse amplitude (i.e., $I_0$) but the switching probability is sufficient amplitude and duration to excite the vast majority of IP states into OPP orbits. This dynamics is thus an important and fundamental characteristic of a biaxial macrospin subject to a spin-transfer torque and demands a physical and mathematical explanation.

III. ORTHOGONAL DRIFT BIASING AT THE SEPARATRIX

To explain this phenomena we consider a scenario where a fixed current is sustaining a stable OOP precessional state ($I > I_{OOP}$). As discussed in the previous section, the macrospin’s steady-state dynamics trace a constant energy orbit, which is a fixed point of the averaged energy dynamics. Changing the current will alter the fixed point and the macrospin will diffuse to a new constant energy trajectory. If changes in the driving current are made slowly enough, then relaxation dynamics will ensure that the energy of the macrospin’s precessional orbits evolves adiabatically with the current. In turn, the macrospin’s average energy will trace a sequence of fixed points. When $I = I_{OOP}$, the structure of the LLGS drift at the separatrix (averaged over one $\epsilon = 0$ revolution) will then influence which IP basin ($m_i < 0$ or $m_i > 0$) the magnetization relaxes into.

To make these statements quantitative, we first parametrize the energy separatrix and project the complete LLGS dynamics (2) onto both its tangent and normal. As shown in Fig. 1(b), the energy separatrix is an intersection of two great circles (shown in black and purple). We denote by $y^{1,2}(x)$ the circles composing the separatrix, where $x$ is the coordinate.
FIG. 4. Relaxed configuration of the Bloch sphere as a function of initial magnetization for $D = 10$, $\alpha = 0.04$, and $\omega = 2.5 \omega_c$, where colors white/black imply relaxation into P/AP basins, respectively. We show the effect of an initially constant ($I_0 = 1.5 I_c$) 0.27 ns T current pulse followed by an exponential decay (with the pulse polarity favoring the P basin) for different temperatures $\xi = 5714$ [left column, (a)–(c)] and $\xi = 80$ [right column, (d)–(f)]. From top to bottom, the exponential relaxation time scale $\tau_I = 0.01, 0.15, 0.3$ ns T. (Physical times are obtained upon dividing by $\mu_0 H_k$.). For slow enough current decays, the magnetization relaxes into the P basin nearly deterministically. The dashed green line shows the dynamical separatrix.

FIG. 5. Switching probability as a function of pulse decay time for a model with $D = 10$, $\alpha = 0.04$, and $\omega = 2.5 \omega_c$. Physical time is obtained upon dividing by $\mu_0 H_k$. The switching probabilities were computed by first driving the magnetization with a constant ($I_0 = 1.5 I_c$) 0.27 ns T current pulse followed by an exponential decay. Higher temperatures lead to lower overall switching probability consistent with the increased thermal noise.

on the circle and 1,2 correspond to the black/purple circle, respectively. The tangent to the separatrix will be $\gamma_1^2(s) = \partial_s \gamma_1^2$ and its normal is given by $\gamma_1^2(s) = \gamma_1^2 \times \gamma_1^2$ (shown as green and red arrows, respectively, in Fig. 1). By noting that at $\epsilon = 0$ the magnetization components must satisfy $Dm^2_z = m^2_z$:

$$
\gamma_1^2(s) = \left( \pm \sqrt{D/D + 1} \sin(s), \cos(s), \frac{1}{\sqrt{D + 1}} \sin(s) \right),
$$

(6)

$$
\gamma_1^2(s) = \left( \pm \sqrt{D/D + 1} \cos(s), -\sin(s), \frac{1}{\sqrt{D + 1}} \cos(s) \right),
$$

(7)

$$
\gamma_1^2(s) = \frac{1}{\sqrt{D + 1}} (1, 0, \mp \sqrt{D}),
$$

(8)

with $s \in [0, 2\pi]$ and $\gamma_1^2(0)$ is a unit vector along the y axis. Increasing $s$ traces the circle along $\gamma_1^2$ and $\gamma_1^2$. 

184412-5
Projecting the magnetization dynamics onto \( y^{1/2}(s) \) and \( y_{\perp}^{1/2}(s) \) gives (see Appendix A)

\[
\mathbf{m} \cdot y^{1/2}(s) = 2\sqrt{D} \left[ \sin(s) + \frac{\alpha}{\pi} \frac{I}{I_c} (1 \mp \tan \omega \tan \omega_c) \right],
\]

\( m \cdot y_{\perp}^{1/2}(s) = 2\sqrt{D} \left[ \pm \sin(s) + \frac{1}{\pi} \frac{I}{I_c} \left( 1 \mp \frac{\tan \omega}{\tan \omega_c} \right) \right],
\]

(9) (10)

where the critical tilt, as mentioned earlier, is \( \omega_c = \tan^{-1}(1/\sqrt{D}) \). (As a reminder, \( \omega > \omega_c \) is assumed in this analysis, as this condition must be satisfied to have stable OOP precessional states.)

On the separatrix, where the period of conservative trajectories formally diverges [7], we see that the time scale for drifting across the separatrix is a factor of \( 1/\alpha (\sim 20) \) larger than that for precessing along it. We thus consider only the portion of the separatrix that bounds the OOP basin \( s \in [0, \pi] \) and compute the average net drift orthogonal to the separatrix:

\[
\langle \mathbf{m} \cdot y_{\perp}^{1/2} \rangle_{\text{orbit}} = \frac{2\sqrt{D}}{\pi} \left[ \pm 1 + \frac{I}{I_c} \left( 1 \mp \frac{\tan \omega}{\tan \omega_c} \right) \right],
\]

(11)

where \( \langle \cdot \rangle_{\text{orbit}} \) implies averaging over the coordinate range \( s \in [0, \pi] \). Given the convention chosen for the orientation of the normals to the separatrix [see Fig. 1(b)], a positive average orthogonal flow \( (\mathbf{m} \cdot y_{\perp}^{1/2})_{\text{orbit}} > 0 \) will always bias exiting the separatrix into the P basin. This is the case whenever

\[
\left( \frac{\tan \omega}{\tan \omega_c} + 1 \right)^{-1} < \frac{I}{I_c} < \left( \frac{\tan \omega}{\tan \omega_c} - 1 \right)^{-1}.
\]

(12)

Since \( I_{\text{OOP}} = I_c/(\tan \omega/\tan \omega_c) > I_c/(1 + \tan \omega/\tan \omega_c) \), this biased orthogonal drift effect will always occur whenever the magnetization crosses the separatrix for \( I = I_{\text{OOP}} \). We now proceed to show how this leads the magnetization to relax into a specific IP basin upon slowly reducing the current sustaining OOP precessional orbits.

**IV. NEAR DETERMINISTIC RELAXATION**

We will now determine the time scales, for which the magnetization will relax to its energy fixed point if perturbed, to determine the requirements on the pulse decay time for reliable magnetization reversal. Upon linearizing the energy evolution equations around \( \epsilon_0 \) fixed point (\( \epsilon \to \epsilon_0 + \delta \epsilon \)) (see Appendix B), the perturbations will be governed by dynamics which exponentially decay with time scale \( \tau_{\text{relax}}(I) \). Figure 6 shows how the relaxation rate of perturbations to a given steady-state precessional state is expected to change as a function of currents \( I > I_{\text{OOP}} \) and varying temperature for a sample with \( D = 10, \alpha = 0.04, \omega = 2.5 \omega_c \). Larger currents and temperatures are seen to favor a faster relaxation of the magnetization dynamics.

If temporal variations of the current happen on a time scale \( \tau_I > \tau_{\text{relax}} \), the magnetization will quickly respond to any destabilizing effects and continuously trace nearly constant energy orbits (the adiabatic condition). If, on the other hand, \( \tau_I < \tau_{\text{relax}} \), the magnetization will be in an out-of-equilibrium state which cannot be characterized with energy averaging techniques.

This model thus captures the physics of the situation we simulated numerically in Sec. II, a case in which a current \( I > I_{\text{OOP}} \) initially sustains a stable OOP precessional orbit (Figs. 4 and 5) and is subsequently reduced. If the current is decreased slowly enough for the adiabaticity conditions to be satisfied, the magnetization will experience an orthogonal drift biasing effect and nearly deterministically switch into the P or AP basin depending on the current’s polarity. Noise will perturb these deterministic dynamics, causing the magnetization to occasionally jump into the unbiased IP basin even under adiabaticity conditions whenever the effective energy barrier separating the IP/OOP basins becomes comparable to the thermal noise strength. This will happen as the magnetization approaches very close to the separatrix. For a more detailed quantitative exposition of these effects, the precise orbital behavior near the separatrix (and not just the constant energy orbit averaging description) must be taken into account due to the constant energy orbit averaging method breaking down at the separatrix.

At lower temperatures, however, we see our model capturing the relevant time scales of the switching dynamics quite well. In fact, for current decay time scales comparable to the maximum relaxation time scale (\( \tau_I \sim \max[\tau_{\text{relax}}] \)) we see that the switching probability plotted in Fig. 5 approaches 1 (e.g., for \( \xi = 5714, \max[\tau_{\text{relax}}] \approx 0.35 \) ns T and high switching probability is seen to take place for current decay time scales \( \tau_I \approx 0.2 \) ns T).

It should be pointed out that even though the constant energy orbit averaging technique is not capable of capturing thermally activated behavior at the separatrix, it can be used to characterize the time scales for dynamical relaxation for larger energy orbits. This is due to the drift-driven character of on-orbit relaxation for which noise related contributions
average to zero and can be shown to be insensitive to the divergence in the orbital period at the separatrix. As such, inducing adiabaticity through slowly varying current pulses is sufficient for demonstrating the orthogonal drift biasing effect.

V. EFFECT OF INITIAL CURRENT

The model we have described further predicts that the final magnetization state only depends on the rate at which the current is decreased, not the initial value of the current that sustains the OPP orbits. We have confirmed this result by conducting numerical simulations for different initial currents with the same relaxation rate of the current. The results are shown in Fig. 7 for initial currents of $I = 1.5I_c$, $2.5I_c$, and $3.5I_c$, and a relaxation time of $\tau_I = 0.01$ ns T. We see that changing the initial current intensity has no effect on the biasing of the relaxation. Thus the orthogonal drift biasing has been shown to depend exclusively on the LLGS dynamics when the current is varied adiabatically.

VI. CONCLUSION

In summary, we have demonstrated that an adiabatically decreasing current pulse leads to highly reliable precessional switching and explained this phenomena within the context of a macrospin model, identifying the time scales that govern adiabatic current variations. These results can be tested on orthogonal spin-transfer torque devices as well as other types of spin-transfer torque oscillators. Our theory makes specific predictions for the switching probability as a function of the pulse decay time and temperature. The model also makes a strong prediction that the switching probability will be independent of the initial current that sustains the out-of-plane precessional orbit. Furthermore, for a slowly decaying current pulse the final magnetization state is also insensitive to the pulse shape and area, only depending on the pulse polarity.

APPENDIX A: ORTHOGONAL DRIFT DYNAMICS ON THE SEPARATRIX

Here we derive the projections of the LLGS dynamics (2) on the $\epsilon = 0$ separatrix starting from the LLGS equation:

$$\dot{m} = m \times h_{\text{eff}} - \alpha m \times (m \times h_{\text{eff}}) - \alpha I m \times (m \times \hat{n}_p).$$  (A1)
To do so we first rewrite the parametrization employed in Eq. (6):

\[
\begin{align*}
\psi^{1,2}(s) &= \left( \pm \sqrt{\frac{D}{D+1}} \sin(s), \cos(s), \frac{1}{\sqrt{D+1}} \sin(s) \right), \\
\psi^{1,2}_\perp(s) &= \left( \pm \sqrt{\frac{D}{D+1}} \cos(s), -\sin(s), \frac{1}{\sqrt{D+1}} \cos(s) \right), \\
\psi^{1,2}_\parallel(s) &= \frac{1}{\sqrt{D+1}} (1,0,\pm\sqrt{D}).
\end{align*}
\]

The effective field for a biaxial macrospin is given by \( \mathbf{h}_{\text{eff}} = -\nabla \psi = -\nabla_{m}(Dm_x^2 - m_z^2) \) and the spin-polarization axis \( \mathbf{n}_p = (\cos \omega, 0, \sin \omega) \) is tilted by an angle \( \omega \) with respect to the easy axis. On the separatrix:

\[
\begin{align*}
\mathbf{m} \times \mathbf{h}_{\text{eff}} &= -2 \left( \frac{D}{\sqrt{D+1}} \sin(s) \cos(s), \mp \sqrt{D} \sin^2(s), \pm \frac{D}{\sqrt{D+1}} \sin(s) \cos(s) \right), \\
\mathbf{m} \times \mathbf{n}_p &= \left[ \sin \omega \cos(s), \frac{\cos \omega}{\sqrt{D+1}} (1 \mp \sqrt{D} \tan \omega), \cos \omega \cos(s) \right],
\end{align*}
\]

where the portion of the separatrix bounding the OOP\(^+\) basin corresponds to \( s \in [0, \pi] \). Employing the vector identities \( \mathbf{y}_\perp \cdot (\mathbf{m} \times A) = A \cdot (\mathbf{y}_\perp \times \mathbf{m}) = \mathbf{A} \cdot \mathbf{y}_\parallel \) (conversely \( \mathbf{y}_\parallel \times \mathbf{m} = -\mathbf{y}_\perp \)) where \( A \) is any vector, gives Eq. (9) in the main text.

**APPENDIX B: ENERGY RELAXATION DYNAMICS**

In this Appendix we derive the time scale for magnetic relaxation onto a stable OOP limit cycle orbit with energy \( \epsilon_0 \) in the presence of a driving current \( I \). First, we note that form of the energy equation is as follows [7]:

\[
\dot{\epsilon} = -\alpha f_D(\epsilon, \tilde{I}) + g(\epsilon) \cdot \hat{W}.
\]

For a macrospin precessing in the OOP\(^+\) basin this equation is [7]

\[
\begin{align*}
\dot{\epsilon} = \frac{\pi \alpha}{\eta_0(\gamma)} \frac{D(D+1)}{D(1-\gamma^2) + 1} \left\{ 
\pm \tilde{I} (1 - \gamma^2) - \frac{2}{\pi} \sqrt{D(1-\gamma^2) + 1} \left[ \eta_0(\gamma) - \frac{\gamma^2}{D(1-\gamma^2) + 1} \eta_0(\gamma) \right] \right\} \\
+ h(\epsilon) + \frac{2 \alpha}{\xi} \frac{D(D+1)}{D(1-\gamma^2) + 1} \frac{1}{\eta_0(\gamma)} \left( \eta_0(\gamma) - \frac{\gamma^2}{D(1-\gamma^2) + 1} \eta_0(\gamma) \right) \cdot \hat{W},
\end{align*}
\]

\[
h(\epsilon) = \frac{\alpha}{\xi} \frac{D(1-\gamma^2) + 1}{1-\gamma^2} \left[ 1 - \left( \frac{D(1-\gamma^2) + 2}{D(1-\gamma^2) + 1} \right) \frac{E[1-\gamma^2]}{K[1-\gamma^2]} + \frac{1}{\gamma^2(2-\gamma^2)} \left( \frac{E[1-\gamma^2]}{K[1-\gamma^2]} \right)^2 \right] + \frac{\alpha}{\xi} \frac{D(1+\gamma^2) + 1}{D(1-\gamma^2) + 1},
\]

where \( \eta_0(\gamma) = K[1 - \gamma^2] \) and \( \eta_0(\gamma) = E(1 - \gamma^2) \) are expressed in terms of complete elliptic integrals of the first and second kind, \( \gamma(\epsilon) = \epsilon(D+1)/(D(1+\epsilon)) \) depends on the energy \( \epsilon \), and \( h(\epsilon) \) is a drift-diffusion correction term. The stochastic contribution \( \hat{W} \) here has zero mean and unit variance; the multiplicative noise \( \epsilon \cdot \hat{W} \) is now interpreted in the Itô sense.

Upon linearizing (B2) around an \( \epsilon_0 \) fixed point \( (\epsilon \rightarrow \epsilon_0 + \delta \epsilon) \), the deterministic portion of the dynamics governing perturbations \( \delta \epsilon \) will be to first order:

\[
\delta \dot{\epsilon} = -\alpha [\hat{\alpha}_f f_D(\epsilon, \tilde{I})]_{\epsilon=\epsilon_0} \delta \epsilon,
\]

whose solution is

\[
\delta \epsilon(t) = \delta \epsilon_0 \exp \left[ -\frac{t}{\tau_{\text{relax}}} \right],
\]

\[
\tau_{\text{relax}} = [\hat{\alpha}_f f_D(\epsilon, \tilde{I})]_{\epsilon=\epsilon_0}^{-1}
\]

[10] The projection along a third orthogonal axis is a dependent quantity arising from our choice of a fixed modulus magnetization.

[13] A tilted spin-polarization axis allows modeling a spin torque that results from more than one “polarizing” layer in a spin-valve (or MTJ) stack or, more generally, a free layer that has an easy axis tilted relative to the spin-polarization axis.

[19] $I_c$ is denoted the critical switching current for this reason.
